Stepwise Multiple Elimination using Linear Transforms: An alternative approach to SRME for stacking multiple-free near offsets in the Barents Sea
Anthony Hardwick*, Carl Lang and Bent Kjølhamar, TGS.

Summary
A novel, de-aliased method called Stepwise Multiple Elimination using Linear Transforms (SMELT) is introduced as an alternative to 2-D Surface Related Multiple Elimination (SRME) to remove problematic multiples on the near-to-mid offsets of common midpoint (CMP) gathers in the south-western Barents Sea. A locally strong Base Quaternary reflector contaminates the SRME multiple model with severe amplitude errors that propagate through the underlying and prospective Triassic-Permian sequence. Adaptive subtraction of this model in any domain leads to the deterioration of primary energy in the target interval. No such deterioration is seen after the application of SMELT, which when used in conjunction with other demultiple processes effective on the mid-to-far offsets, allow the full offset range to be stacked.

Introduction
In 2009 TGS acquired 2770 km² of multi-client seismic data in the south-western Barents Sea across the Hoop Fault Complex with a further 800 km² and extension programs planned for 2010, covering acreage nominated in the recent 21st Norwegian licence round.

The Hoop Fault Complex (HFC) derives its name from the vessel “de Hoop” used by Dutch explorer Willem Barentsz and is a swarm of NE-SW trending normal faults with a strike-slip component cutting across the Loppa High and the Bjarneland Platform (Gabrielsen et al., 1990). The survey (figure 1) images the northernmost part of the Maud Basin and the greater part of the platform immediately to the NE. The area was subject to significant uplift in late Jurassic/early Cretaceous times resulting in late Cenozoic glacial erosion estimated to be in the region of 1900 metres (Løseth et al., 1992). Across the survey a strong unconformable Base Quaternary reflector (BQU) follows the water bottom at an interval of approximately 60 milliseconds strongly attenuating primary energy.

The interaction of multiples, both surface related and internal, generated within the water-bottom – BQU layer compromise the ability of SRME (Berkhout 1982, Verschuur et al., 1992) to correctly predict multiple and preserve amplitudes within the potentially prospective underlying Triassic-Permian sequence. An alternative, de-aliased demultiple method, seen to preserve amplitudes, is presented in the following sections, termed Stepwise Multiple Elimination using Linear Transforms (SMELT), capable of removing multiple on the near-mid offsets.

Defining the Problem
SRME involves two stages, multiple prediction and primary-multiple separation. Despite major advances, amplitude errors and imperfections in the predicted multiple model remain a challenge in the second separation stage. Conventional least-squares (L-2) adaptive matching-filtering techniques can lead to residual multiple energy and the deterioration of the primaries in such instances. Abma et al., (2005) show that L-1 adaptive subtraction fairs little better and recent implementations such as curvelet-domain
Stepwise Multiple Elimination using Linear Transforms

separation (Herrmann et al., 2007) still deteriorate in the presence of significant amplitude errors.

In the HFC area amplitude errors in the predicted multiple model are clearly apparent (figure 2(b)). The amplitude error worsens as the BQU-water layer becomes more extensive and a short period reverberation dominates the multiple model through the Triassic and Permian, not present in the input data (figure 2(a)).

Stepwise Multiple Elimination using Linear Transforms (SMELT)

The local failure of SRME to preserve amplitudes related to the strong BQU reflection creates a challenge to stack multiple-free near offsets. The new process we term SMELT addresses this problem. The SMELT “multiple model” (figure 3) is gradually built up by a series of linear transforms in the CMP domain after flattening multiples with a constant normal moveout correction (NMO), in steps between water and maximum peg-leg velocity. For a zero offset intercept \( \tau \) and apparent slowness \( p \), the amplitude \( F(\tau, p) \) in the tau-\( p \) domain is described discretely by

\[
F(\tau, p) = \sum_{i=1}^{n} F(x_i, \tau + px_i)
\]  

(Turner, 1990), where \( n \) is the number of traces used in the transform and \( x \) is the offset of the trace on the input CMP gather. If multiples on the CMP gather are perfectly flattened prior to transformation, then the velocity \( v \to \infty \), so the apparent slowness

\[
p = \frac{x}{tv^2} \to 0,
\]  

where \( t \) is time on the input CMP gather. In the limit, equation (1) therefore reduces to

\[
F(\tau, p) = \sum_{i=1}^{n} F(x_i, \tau).
\]  

In the SMELT process only multiples flattened with a constant NMO are passed through the forward-inverse tau-\( p \) transform pair with the correct amplitude reconstructed. As a zero \( p \)-range cannot be transformed in practice, the actual range is related to the velocity step \( \Delta v \) centered on \( p=0 \). As we want to account for slight under- and over-correction as well as non-hyperbolic/anisotropic effects, following on from equation (2) the effective \( p \)-range transformed is

\[
\left[ \frac{1}{2} \left( \frac{x}{tv - \frac{\Delta v}{2}} \right)^2 - \frac{x}{tv + \frac{\Delta v}{2}} \right],
\]  

where \( v_{\text{const}} \) is between water velocity and maximum peg-leg velocity of interest. At each step the true multiple is subtracted from the input data in the CMP domain within a window. As the multiple is flattened in each velocity step prior to transformation the process is de-aliased. Only a very small number of \( p \)-traces are required under normal aliasing criteria in the tau-\( p \) domain, making the process extremely cost-effective.

Results

Figure 4 shows the application of SMELT on a CMP gather after tau-\( p \) processing in the shot and receiver domain, prior to radon demultiple. Not only does SMELT perform better than 2-D SRME on the near offsets in this example, difference displays (figure 4(d)) reveal no deterioration of primary. The superior result provided by SMELT is also apparent on a full offset stack out to 55° angle of incidence with no inner trace muting applied (figure 5(b)).

Conclusions

The locally strong Base Quaternary reflector in the HFC area associated with uplift and subsequent widespread glacial erosion generates significant amplitude discrepancies in the SRME model. Deterioration of primary energy in the prospective underlying Triassic-Permian sequence is inevitable with 2-D adaptive subtraction methods. SMELT provides a very effective, de-aliased and
Stepwise Multiple Elimination using Linear Transforms

cost-efficient alternative to stacking the near offsets with good preservation of primary amplitudes in this region of the south-western Barents Sea.

Acknowledgements

The authors would like to thank TGS for permission to show the data examples and all colleagues in Bedford and Asker involved in the HFC project. We also thank colleagues in Houston for feedback in the preparation of this abstract.
